BACKGROUND OF THE INVENTION

Field of the Invention

The invention relates to a method for forward modeling the spatial distribution faults and fractures in a geologic formation.

5

Background of the invention

The prediction of faulting and fracturing is very important in oil and gas exploration and production. Seismic data is often used to find faults that bound or delineate hydrocarbon reservoirs. However, due to the limited resolution of seismic data, the details of the faulting in the subsurface may not be determinable.

10

Knowledge of the distribution of the fractures in a geologic formation is of great importance first for optimizing the location and the spacing between the wells that are to be drilled through an oil formation. Furthermore, the geometry of the fracture network conditions influences the displacement of fluids on the reservoir scale as well as on the local scale, where it determines the elementary matrix blocks in which the oil is trapped. Knowledge of the distribution of the fractures is thus also very useful at a later stage for the reservoir engineer who wants to extrapolate the production curves and to calibrate the models simulating reservoirs. The development of naturally fractured reservoirs thus requires better knowledge of the geometry of the fracture networks and of their contribution to the orientation of the flows.

15

20

Seismic data are commonly used for acquiring information about the subsurface of the Earth. Changes in the elastic properties of subsurface rocks appear as seismic reflections. Such changes in the properties of the rocks typically occur at boundaries between geologic formations, at fractures and at faults. The vertical resolution of the seismic method is approximately one-quarter wavelength of the seismic wave and, in typical situations, is of the order of 10 meters. The horizontal resolution is determined by the size of the Fresnel zone for the seismic wave at the depth of interest and may be tens or even hundreds of meters. By using sophisticated processing techniques, such as prestack migration taking advantage of data redundancy, the positions of the seismic reflectors may be more accurately determined up to the spacing of the geophones. Nevertheless, it is only the major seismic reflectors that may be determined by this method. Additional information about finer scale faulting and fracturing would be very useful in predicting flow characteristics of a hydrocarbon reservoir and in development of a program for optimization of hydrocarbon recovery. Since all faults are not clearly delineated by the seismic, it would also be useful to verify the location of faults that are difficult to see seismically are interpreted in a consistent manner.

United States Patent 5,953,680 issued to *Divies et al* describes a method for creating a two-dimensional (2-D) kinematic model of a geologic basin affected by faults. The basin is divided into a number of layers or banks whose geometric positions are known. The tectonic deformation of each modeled layer is determined separately by taking its thickness and length into account, with

compaction being taken into account. The basic assumption is that the banks are competent units that undergo little deformation. The method does not include the material properties of the rocks as part of the input and hence is not particularly well suited for determining the effects of loading.

5

United States Patent 5,838,634 issued to *Jones et al* obtains geologic models of the subsurface that are optimized to match as closely as feasible geologic constraints known or derived from observed geologic data. The models also conform to geophysically based constraints indicated by seismic survey data.

10 It accounts for geophysical information by converting the geologic model to synthetic seismic traces, accounting for fluid saturation, and comparing these traces with observed seismic trace data. The process perturbs the rock properties in the geologic model until the geologic model is consistent with geologic and geophysical data and interpretations. However, the issue of how to obtain a
15 reasonable fine-scale geologic model is not addressed.

Broadly speaking, four different ways have been used to model the problem of geologic modeling of the subsurface on a wide range of scales. The first approach is to use statistics to capture the number and orientation of faults at
20 one scale or in one deformational setting and to use simple statistical rules to extrapolate this information to other scales or deformational settings. An example of this is United States patent 5,659,135 to *Cacas*.

A second method that has been used is to use finite element modeling to

solve the stress field from given input deformations. Once stress exceeds a given amount a fault or fracture is drawn in by hand and then the model simulation can continue. Alternatively, faulting patterns are put in by hand, and the formation is pressured up to estimate a stress distribution. The rock is modeled is a network of
5 distinct elastic elements, connected by elastic connection to its outer boundaries. The main obstacles to the application of such methods for geologic modeling are the computer time and the human interaction that is involved. The computer time roughly increases as the square of the number of nodes in the model and the models must be continuously interacted with by the user to put in new faults as
10 they are believed to have occurred.

In a third method, large scale rules of geometry or faulting seen in the subsurface under certain deformation conditions are quantified and applied to forward modeling software. These forward models usually consist of a well-
15 defined set of large scale shapes that are expected to be produced. An example of this is United States Patent 5,661,698 issued to *Cacas*, which starts out with a group of major faults detected by means of an exploration of the zone, and additional minor faults that have not been detected during the exploration. The fractal characteristics of the major faults are determined and the additional minor
20 faults are constrained to have the same fractal characteristics. The fractal characteristics used include the fractal dimension of the fault network and a density function defining a distribution of lengths of the faults. Such a method does not account for differences in the rock properties of different geologic formations and differences in their mode of faulting.

A fourth method that has been used is the so-called "distinct element model." It uses small scale rules of stress and strain to move nodes in a model to predict faulting and fracturing. It is well suited for problems of geologic fracturing but suffers from the drawback of being computationally slow. In addition, the methods are not particularly user friendly in terms of user interface used for specification of the model and of the material properties.

There is a need for an invention that is able to simulate faulting and fracturing on a variety of scales in a subsurface geological model. Such an invention should preferably take into account the differences in material strength of different types of rocks. Such an invention should also be computationally fast. In addition, it is preferable that the invention should be user friendly in that specification of the rock properties and loading be easily input and that the invention be able to provide graphical displays of the deformation process. The present invention satisfies this need.

SUMMARY OF THE INVENTION

The present invention is a computer-implemented method for modeling of faulting and fracturing that uses "small scale rules" to produce large scale results. Organizationally, the software for the invention is made up of two parts. One part is a user interface for inputting deformations, pre-existing faults and fractures, and material rock properties. The second part of the software is the code that solves the motion of each point or node in the subsurface volume defined by the user

interface. The solution code solves the forces on each node and their resulting movement. Faults and fractures occur as the nodes are widely separated and the forces between the nodes (that are based on the node locations) are changed. The user interface may be used to produce a quick look at the deformation results and
5 to view the results of the full simulation.

Functionally, as with all modeling programs, the present invention has two primary components. The first is the model definition and the second is the response of the model to the applied deformation and stresses. In the present
10 invention, there is a third important component: a graphical user interface that is very useful in both the model definition and in viewing the results of the applied deformation and stresses.

The model may be defined in one of three modes. In the aerial mode, the
15 model is 2-dimensional with the material and a substrate on a horizontal plane. A nodal pattern that, in the preferred embodiment, is a regular triangular lattice is used for the model definition, although other nodal patterns may also be used. An alternate embodiment of the invention allows for randomly positioned nodes in a so-called "disordered lattice." The deformation can be applied to any point in the
20 substrate and the resulting response determined. The cross-sectional mode is similar to the aerial mode except that the nodes are in a vertical cross section and gravity is included in the model. The substrate attachment is limited to the bottom and sides of the material region. The 3-D model is an extension into a third dimension of the 2-D model and deformation may be applied to the bottom and

four sides of the material region.

The computational method used in solving for the deformation is a modified over-relaxation approach. In the basic over-relaxation method, equilibrium is reached by moving each node a distance proportional to the force acting on the node. The constant of proportionality is called the over-relaxation constant and optimal methods for selecting it are known. In each relaxation cycle, each node is moved and the relaxation cycles repeated until no node is moved further than a threshold distance, which is called the relaxation threshold. In the present invention, the over-relaxation is concentrated in those nodes where the greatest movement occurs. This significantly speeds up the computation time.

A novel aspect of the invention is the conditioning of the model. In the real world, the interpretation of the subsurface structure starts with observations of large scale fracturing and faulting. In one aspect of the invention, based upon the observed large-scale deformations, the user derives an initial geometry of the unfaulted material. Since it is clearly desirable that the end result of applying stresses to the model should at least duplicate the observed large-scale deformations, the model is weakened at the reconstructed fault positions so that upon application of the stresses, there will be a predisposition to produce the observed large-scale fractures and faults. The conditioning step is made easier in the present invention by use of the graphical user interface

Another novel aspect of the invention is the use of an "anticipate" step to

get a quick solution to the deformation. The anticipate process is particularly useful in the definition of the deformation that is applied to the model. It is also useful in the conditioning of the initial trial model: comparison of the output of the anticipate step with the actual observed deformation serves as a check on the initial model. If the agreement is reasonable, then the initial trial model is used. If, however, the agreement is not good, a different initial trial model is used.

BRIEF DESCRIPTION OF THE DRAWINGS

For detailed understanding of the present invention, references should be made to the following detailed description of the preferred embodiment, taken in conjunction with the accompanying drawings, in which like elements have been given like numerals and wherein:

Figure 1 is a flow chart of the important steps of the invention.

Figures 2a - 2B show the triangular nodal configuration for the aerial and 2-D of the model.

Figure 3a illustrates some of the parameters required for a beam model.

Figure 3b illustrates the steps by which the deformation process is carried out and the bonds in the model are broken.

Figures 4a - 4c show the manner in which boundary conditions are handled in the invention.

DETAILED DESCRIPTION OF THE INVENTION

An overview of the invention

15 Turning now to **Fig. 1**, a flow chart of the major steps of the present invention is depicted. The first step in the invention is to select a mode of definition of the subsurface **101**. This is described further below in reference to **Figs. 2a - 2b**. This step defines the boundaries of the model and the nodal configuration therein. The mode of definition may be aerial, cross-sectional or 3-
20 D. Within the model, a plurality of interconnected nodes that characterize the geometry of the model are defined. In a preferred embodiment of the invention, the nodal pattern is a regular triangular lattice, although other patterns, such as a random lattice, may also be used. The user may also specify the number of nodes in and the aspect ratio of the model. This is conveniently done using the GUI.

The GUI is discussed below in reference to Figs. 6 - 13.

Within the framework of the nodal geometry defined at **101**, the material properties of model are input **103**. The nodes are interconnected by either springs
5 (bonds) or beams having elastic properties and breaking strengths related to the physical model. In a preferred embodiment of the invention, the springs are linear elastic springs. In an alternate embodiment of the invention, any user-specified stress-strain curve may be used. The user may also specify independently a repulsion between the nodes. Also input is the optional conditioning of the model
10 (discussed below with reference to **107**). The model definition and the conditioning are carried out using the GUI.

Once the model has been defined, the deformations are applied to the model **109**. The result of deformation is to produce a deformed model with
15 faulting and fracturing therein. This determination of the deformation process is carried out using a Dynamic Range Relaxation model **115** that is discussed in further detail below. The resulting deformed structure **117** from the model simulates the geological processes that occur in the real world and may be analyzed by those versed in the art to determine reservoir characteristics for a
20 hydrocarbon reservoir and used in a development program.

Those versed in the art would recognize that the full-fledged numerical simulation is computationally expensive. There are no guarantees that the end result **117** will actually have the major features that are actually observed in the

real world. In one aspect of the invention, an Anticipate process 111, discussed below, is used to provide a quick and dirty look at the possible outcome of the applied deformations 109. Based on an examination of the output of the Anticipate process, the model and the applied deformations may be adjusted 113 if necessary.

Another aspect of the invention is a conditioning process. The geologic interpretation process starts with the final position of the faults, and, in particular, the large-scale faults 105. These could be observations of surface faulting, as well as faults interpreted from the wellbore. It is essential that the deformed structure 117 include in it at least these large scale faults. Usually, the initial model is obtained from basic principles that would be familiar to a structural geologist. The observed fault structure is "undeformed" by reversing the process that produced the faulting in the first place. This is entirely a kinematic procedure that repositions the various fault blocks consistent with the laws of gravity and conservation of mass to the initial position they must have been in before the deformation started. This process is sometimes referred to as palinspastic reconstruction. Application of deformation to the FramView model usually results in the observed large-scale deformation. However, in some cases this may not be enough. In such cases, the conditioning of the model is carried out. In the conditioning process, the model is weakened at the reconstructed fault positions so that after deformation of the model, fracturing and faulting are more likely at these positions. This is discussed below in the section on "Conditioning the Model."

The graphical user interface plays an important role in all of these steps. It is used in defining the nodal structure of the model, the strengths of the bonds between the nodes, the specification of the stresses, the display of the deformed structure and in the conditioning process. This is described below in reference to

Figs. 6 - 13.

The model definition

Turning now to **Fig. 2a**, an aerial model is depicted. In the picture above, two sets of nodes are shown. The lower plane is a set of nodes **201a, 201b, 201c, . . . 201n** called the "substrate". The upper plane consists of the nodes **211a, 211b, 211c . . . 211f** that make up the material itself. A line is drawn connecting each of the nodes in the material with its neighboring nodes. These lines represent springs (or bonds), beams, or attractive forces between the nodes. Note that there are two sets of springs. One set is in the plane of the nodes; the other extends down to one of the nodes in the substrate. In a way, this picture is incorrect, because the actual model is really only two-dimensional. The entire model lies in a plane, so that the substrate nodes are not really below the material nodes, but instead lie in the same plane with the material nodes.

To deform the material, the substrate nodes are moved according to deformation arrows defined in the model interface. In the aerial mode, deformation arrows (not shown) can be applied at any point in the substrate. These are applied in a point and click manner. In order to specify the deformation

between the user input arrows, a calculation is done to map the specified deformation arrows to every point in the substrate. As the substrate nodes are moved, the material nodes are "pulled along" and are separated from each other. As part of the model definition, a distribution of breaking strengths is defined in the interface. In a spring model, the distribution of breaking strengths has an equivalent distribution of breaking lengths. Hereafter, the two terms may be used interchangeably. From this distribution of breaking lengths, a breaking distance has been assigned to each spring. If the length of any spring exceeds its breaking distance, that spring is broken and is never re-attached. The distribution of breaking lengths is assigned by giving a mean and the standard deviation of the breaking distances. A random number seed is used to choose one breaking length from the distribution for each spring on the spring network. As soon as the length of a spring connecting two nodes exceeds its breaking length, the spring breaks. By changing the random number seed, a number of realizations can be made from the same breaking distribution.

Optionally, the anticipate function, described below, allows the user to see what a "rubber sheet" deformation would look like without any breaks. This use of the anticipate function as a screening tool allows accurate definition of the deformation arrows.

The software in the user interface is capable of reading in pictures in .gif format and resize them to help position deformation arrows, in the definition of

the material properties and in conditioning the model. This makes it possible for the user to trace results from a scanned picture or file directly into the interface.

Preexisting fractures or faults can be added using the interface.

5 Preexisting faults or fractures are added by drawing line with the interface.

Material regions can be defined within the material. Within these material regions, the distribution of breaking thresholds, spring constants, repulsion and substrate attachment may be defined by using the interface. This allows the modeling of a wide range of earth materials, from the very ductile to very brittle rocks.

10

In the cross-sectional mode, the same features are available as for the aerial mode. In addition, the model includes the effect of gravity. An example of a cross-sectional model is shown in **Fig. 2b**. The substrate attachment is limited to the sides and bottom of the material. As the name implies, in the cross-sectional mode, the model is a vertical cross section of the subsurface of the earth.

15

In the 3-D mode, the same invention has the same capabilities as in the cross-sectional mode. In a preferred embodiment, the nodes are in a triangular configuration and the connection between the nodes is by means of springs. This reduces the computational time compared to other arrangement of nodes and beam connections between the nodes. The deformation may be applied to the bottom and four sides of the volume of the material region.

20

For two dimensions, the nodes are represented by discs, and for three dimensions, the nodes are represented by spheres. The discs or spheres have a characteristic radius r_i . The elastic elements between the nodes are modeled by elastic springs with an equilibrium length l_{ij} that corresponds to the sum $r_i + r_j$.

- 5 The forces acting on the node i can be decomposed into the following:

$f_{i,j}^n$ normal force from node j

f_i^o substrate attachment force

f_i^a boundary attachment force

f_i^e external forces

10 f_o^p force from salt pressure.

The normal force has the form

$$f_{i,j}^n = k_{i,j} \left(|x_i - x_j| - l_{i,j} \right) u_{i,j}^n \quad (1)$$

- where the vector $u_{i,j}$ points from the center of node i to the center of node j . On a
15 macroscopic scale, the spring constant $k_{i,j}$ is related to Young's modulus $k_{i,j} = Ew$

where w is the thickness of the disks in a 2-D model. For practical purposes, the equations are rescaled with a length l corresponding to a typical internode distance, and with a spring constant k corresponding to a typical spring constant.

The corresponding equation is then

$$20 \quad f_{i,j}^n = \kappa_{i,j} \left(|x_i - x_j| - l_{i,j} / l \right) u_{i,j}^n \quad (2)$$

where all lengths are measured in units of l and $\kappa_{i,j} = k_{i,j} / k$. In one embodiment of the invention, repulsive forces are included and a similar repulsive force acts

between all particles in contact with each other. Generally, the force constants for attraction and repulsion need not be identical. The force constant for repulsion is denoted by $\kappa'_{i,j} = k'_{i,j} / k$.

- 5 The substrate attachment force has the form

$$f_i^0 = \kappa_i^0 [x_i^0 - x_i^s] \quad (3)$$

The positions x_i^0 of the substrate attachment points are displaced along with the substrate and impose the boundary interactions on the elastic elements.

- 10 The boundary attachment force has the same form as the internode attachment. The spring constant for this connection is separately specified and is related to the elastic coefficients of the boundaries. Boundary interactions are always repulsive, but may additionally include attractive interactions. Boundary conditions are discussed below.

- 15 The preferred embodiment of the invention includes, optionally, gravity or externally imposed forces such as the addition of an overburden pressure. These forces are discussed below.

- 20 Deformations are imposed on the simulated material from the boundary conditions. These deformations are input into the model via arrows drawn on the interface at user specified locations. These input deformations are "interpolated" between the user specified arrows using the anticipate function results along the

boundaries (or substrate in the aerial model). This defines the movement of every boundary node. When the dynamic range relaxation algorithm is run, each boundary point is moved from its initial ($t = 0$) to its final ($t = 1$) position in small steps. At each time step, the lattice is relaxed according to the dynamic relaxation algorithm. If any spring supersedes (i.e. is equal to or greater than) its maximum elongational force $f_{i,j}^c$, it is irreversibly removed from the lattice and the equilibrium configuration recomputed (i.e. the spring or bond is broken, or removed). Only one spring is removed each iteration, and the spring that exceeds its threshold the most is broken first. When no more springs are broken, the deformation is propagated another time step and the process is repeated.

The spring model provides sufficient shear stiffness in an unfractured, triangular lattice in which each node has 6 neighbors. However, for a randomly generate lattice, the average number of connected neighbors is less than 6, and a spring lattice becomes unstable under shear. When the material is deformed, internal regions may respond by rotation, which produces a material with a very low coefficient of elasticity. In order to prevent this, an alternate embodiment of the invention includes beams connecting the nodes of the lattice. Fig. 3 is an illustration of 4 beams connecting a node to adjacent nodes (not shown) and the sign convention for the rotation angles associated with the beams. All the beam attachments are assumed to move stiffly with the beam.

The linear, normal force $f_{i,j}^n$ has the same form as for the spring

connection. In addition, there is a shear force $\overset{\times}{f}_{i,j}$ acting on node i due to the beam connection with node j .

$$\overset{\times}{f}_{i,j} = \frac{1}{2} \frac{1}{2(1+\nu) + \frac{A l_{i,j}^2}{12I}} \{ \theta_{i,j} + \theta_{j,i} \} \overset{\times}{l}_{i,j} \quad (4)$$

5

where ν is the Poisson's ration, I is the moment of inertia of the cross-section of the beam around the center of the beam and A is the area of the cross-section of the beam. For a rectangular cross section of width w , corresponding to cylindrical particle of width w , the moment of inertia is $I = a^3 w / 12$ where a is the width of the beam, and the area is $A = aw$. The shear force may therefore be expressed in terms of a instead of I

10

$$\overset{\times}{f}_{i,j} = \frac{1}{2} \frac{1}{2(1+\nu) + \left(\frac{l_{i,j}}{l}\right)^2 \left(\frac{l}{a}\right)^2} \{ \theta_{i,j} + \theta_{j,i} \} \overset{\times}{l}_{i,j} \quad (5)$$

In eqs. (4) and (5), $\overset{\times}{l}_{i,j}$ is a unit vector pointing in the direction of the shear force on the i -th particle, as indicated in Fig. 3.

15

For convenience, a shear force constant k_s may be defined as

$$k_s = \frac{1}{2} \frac{1}{2(1+\nu) + \left(\frac{l_{i,j}}{l}\right)^2 \left(\frac{l}{a}\right)^2} \quad (6)$$

The moment about the disc center I due to the bent beam connected to node j is

$$m_{i,j}$$

20

$$m_{i,j} = \frac{1}{2(1+\nu) + \left(\frac{l_{i,j}}{l}\right)^2 \left(\frac{l}{a}\right)^2} \left\{ \left(\frac{l}{l_{i,j}}\right)^2 2(1+\nu) \frac{1}{12} \left(\frac{a}{l}\right)^2 (\theta_{i,j} - \theta_{j,j}) + \frac{1}{2} \left(\frac{2}{3} \theta_{i,j} + \frac{1}{3} \theta_{j,j} \right) \right\} \quad (7)$$

The prefactor of the first angular term may be defined as

$$\gamma_{i,j} = \left(\frac{l}{l_{i,j}}\right)^2 2(1+\nu) \frac{1}{12} \left(\frac{a}{l}\right)^2 \quad (8)$$

In a preferred embodiment of the invention, the Poisson's ratio lies between 0 and 0.5 while a lies between 0 and 1.

Simulations of the beam model are performed in an analogous manner to those of the spring model. The points defining the boundary conditions are displaced in small steps from the initial to the final positions, and at each step, the equilibrium configuration is found for the lattice. However, the beams may break either due to tensional or shear stress, and the rotational aspects of the node motion must be included in the relaxation algorithm.

Dynamic Range Relaxation

Referring again to **Fig. 1**, the step of Dynamic Range Relaxation **115** is discussed. As noted above, the present invention includes a modified Distinct Element Model (DEM). In DEMs, the rock is modeled as a network of distinct elastic elements connected by elastic connections to its outer boundaries. The boundaries are deformed in small steps, and the force equilibrium configuration is

found for each step. The spatial resolution of the prediction depends on the size of the model system measured in units of distinct elements used. The main limiting factor for the practical application of such models to the geologic problems of interest is the long computer time needed to find force equilibrium.

5

Numerous methods exist for the solution of relaxation problems or minimization problems. The problem of finding a force equilibrium is equivalent to a minimization problem since the corresponding elastic energies associated with forces acting on the nodes of a lattice must be minimized to find the force equilibrium configuration. Prior art methods use a brute force solution to the problem at a high computational cost. The computational times for prior art methods, such as conjugate gradient methods, is proportional to L^4 where L is the length of a side in the network measured as the number of distinct elements.

A more direct approach to the problem is over-relaxation: this is also a standard method for solution of minimization problems. In over-relaxation methods, equilibrium is reached by moving each node a distance proportional to the forces acting on the node. The constant of proportionality is called the over-relaxation constant, and optimal choices for it exist. (*Allen 1954*). In each relaxation cycle, each node is moved, and the relaxation cycles are repeated until no node is moved farther than a threshold distance, termed the relaxation threshold. Generally, over-relaxation methods require a number of computations of the same order as a conjugate gradient method.

In damped relaxation methods each node is given a mass and a damping force is associated with each spring. The solution for the overall system is found by numerical integration but the overall computation time is not significantly less than for conventional over-relaxation methods. Some prior art methods have
5 speeded up the relaxation. For example, in block relaxation methods, blocks of many nodes are moved as a rigid body a distance proportional to the net sum of forces acting on the boundaries of the block.

In the present invention, a modified relaxation scheme is used for solving
10 the deformation problem. As noted above, the system to be solved comprises a network of nodes connected by elastic connections. The connections may be of any type and may be represented by any force law. As noted above, they can be springs, bending beams, or rotating rods. Those versed in the art would be familiar with using the method of the present invention to other types of elastic
15 connections between the nodes of the model.

The force $f(x_i, x_j, q_{i,j})$ acting on a node i at position x_i due to contact with node j depends upon the position of node j , x_j , and additional variables $q_{i,j}$ related to the relative configuration of the two nodes, such as their relative angle of
20 rotation about any axis. The net force acting on node i is then given by an equation of the form

$$F_i = \sum_j f(x_i, x_j, q_{i,j}) \quad (9)$$

This includes all the forces discussed above with reference to eq. 1 - 8. In the present invention, an over-relaxation technique is used on the set of eqs. (9).

However, the over-relaxation is concentrated in the region of the model where
5 movement occurs using the following method.

The method of the present invention combines the basic Dynamic Range Relaxation Algorithm (DRRA) with steps that include fracturing and faulting.

This is a novel aspect of the present invention. Prior art techniques, such as finite
10 elements method do not involve the breaking of bonds when the deformation exceeds a prespecified deformation limit. *Cundall* has disclosed a damped method in which fracturing does occur. However, as noted elsewhere, conjugate gradient methods, damped relaxation methods, and finite element methods require much larger computation time than does the present invention. In the present
15 invention, displacements are applied to the boundaries of the model. Turning now to **Fig. 3B**, initially only the boundary points of the model are moved a prespecified fraction of the total displacement to be applied **251**. In a preferred embodiment of the invention, this fraction is .001. After this application of partial displacement of the boundaries, the DRRA given in the following list is carried
20 out.

1. All nodes are relaxed according to a single over-relaxation step.
2. All nodes that move further than the relaxation threshold ε are added to a list A.

3. If list A is empty, that is, no nodes have moved further than the relaxation threshold, move to step 10.
4. The nodes in list A are relaxed sequentially with a single over-relaxation step each.
5. If the displacement of a node exceeds the relaxation threshold ε then this node and all the nodes it interacts with are added to a list B.
6. Each node is only added once to list B.
7. When all nodes in list A have been relaxed, lists A and B are interchanged.
8. If list A is non-empty (that is, at least one node has been moved further than the relaxation threshold ε), return to step 4.
9. Return to step 1.
10. End.

A check is then performed to see if any of the bonds have exceeded their breaking threshold using criteria described below 253. If no bonds have exceeded their breaking threshold, a check is made to see if all the boundary points are at their maximum displacement 255. If the answer is yes, then the simulation is complete and the process stops. If, however, the answer at 255 is "NO", then the displacement of the boundary points is increased 259 and the process repeated starting at 251.

20

If the answer at 253 is "YES", i.e., some bonds have exceeded their breaking point, then only the bond that exceeds its breaking threshold the most is broken 261 and the method proceeds to the **DRRA** discussed above. The process illustrated in **Fig. 3B** will stop when no more bonds are being broken and all the

boundary points are at their maximum displacement.

For the case of models that include salt, the method is modified slightly. If one node that belongs to a salt boundary is displaced, that information is propagated via the pressure to all the other nodes along the salt boundary. All the nodes along the salt boundary must therefore be added to list B if a node on the salt boundary is displaced further than the displacement threshold. Those versed in the art would recognize that a node may interact with more nodes than it is connected to, because repulsive interactions may be present between non-connected nodes. Accordingly all interacting nodes should be added to list B if a node is displaced further than the relaxation threshold.

For the problem of fracturing and faulting in the present invention, this relaxation method is significantly faster than prior art methods mentioned above. For example, in two dimensions, the number of computer time steps for solving the system is proportional to $L^{1.3}$. This compares with a number of time steps for a conjugate gradient scheme of L^4 .

A model with size $L = 500$ typically takes 1.2 hours to run on a IHP-735@ MklI workstation. A comparable conjugate gradient solution would take hundreds or thousands of hours.

BOUNDARY CONDITIONS

An important aspect of the present invention is the application of

deformations. Deformations are imposed by the boundaries; however, the imposition of the interactions depends upon the mode of definition.

For the aerial mode, the deformation is imposed by the movement of the supporting substrate. Each node i of the 2-D network is attached to a corresponding substrate attachment point. Initially, the node position and the substrate attachment point are coincident. The attachment between the nodes and the substrate attachment point is modeled as a weak spring

$$\mathbf{f}_i^0 = \kappa_0 (\mathbf{x}_i - \mathbf{x}_i^0) \quad (10)$$

where κ_0 is the spring constant for the node-substrate coupling relative to the internode spring constant.

A similar torque attachment is used in addition to the linear spring for the aerial beam model, to localize the propagation of rotations. In the beam model, a moment $m_i^0 = -k_{\phi} \phi_i$ acts on each node attached to the substrate where ϕ_i is the angular rotation of node i .

Cross-sectional and 3-D simulations handle boundary conditions differently. Boundary conditions are specified along the outer boundaries of the material only. The boundaries are modeled as particulate walls of discs or spheres. These boundary particles interact with nodes in the material through unbreakable linear springs and repulsive forces.

Referring now to **Fig. 4**, particles (discs or spheres) **301** are lined up along the boundaries. The particles **301** have a diameter $2r_w$ and are spaced a distance d_w apart where d_w is less than r_w . All material particles **302** (particles here referring to a region surrounding a node) within a distance d of the boundary are attached to the nearest wall particle by an unbreakable spring **303** having a spring constant k_w . As per the convention adopted above, this spring constant is normalized relative to the internode spring constant. In addition to the attractive interaction from such springs, repulsive forces act between all overlapping material particles and wall particles. A strong repulsive force is maintained between the wall particles and the adjacent material particles.

During deformation, the walls may be stretched locally. The present invention includes a step for avoiding the possibility of material particles passing through the wall without interaction. This step is implemented prior to applying the dynamic relaxation algorithm to the internal nodes. The steps for cross sectional simulations are as follows:

1. The initial boundaries are filled with a constant spacing d_w is illustrated in **Fig. 4**. This generates a sequence of discs at positions \bar{x}_k for $k = 1, 2, \dots, N$.
2. The boundary discs are displaced to their final positions at the end of the deformation.
3. The distances between adjacent wall particles are measured. If the distance between wall particle k and particle $k+1$ exceeds d_w , new particles are inserted along the line between \bar{x}_k and \bar{x}_{k+1} in the initial configuration in order to

make the separation no greater than d_w in the final configuration.

4. Repeat steps 2 and 3 until no further particles need to be added.

It is important to repeat steps 2 and 3 several times, because the newly entered particles may be displaced into different positions than what was assumed when

- 5 the wall particle distance was calculated in step 2.

A similar technique is used for defining particle walls in 3-D models. For the 3-D case, the process of iterative particle placement has to be modified to fill the wall areas with a sufficiently large density of wall particles. This technique in

- 10 3-D is defined as follows:

Turning now to Fig. 4b, initially, the wall is represented by a set of triangles such as 351a, 351b, 351c. Associated with each vertex of the triangle is a particle, i.e., 353a, 353b and 353c. The iterative refinement procedure for filling
15 in the triangle follows the steps given here:

1. For each triangle in the set of triangles, the maximum distance between any two vertices is measured. If this maximum distance exceeds the placement threshold d_w , the triangle is subdivided into 4 smaller triangles by the
20 points 355a, 355b and 355c.

2. At each vertex in the subdivision, a wall particle is placed.

However, there may already a wall particle in this position due to subdivision of a neighboring triangle. Accordingly, duplication must be resolved.

3. The newly defined triangles are added to the set of triangles and the

original triangle is removed from the list. Step 1 is repeated until no more triangles need to be subdivided.

4. The boundary nodes are then moved to their final positions. Steps 1, 2, and 3 are repeated. With the new set of nodes Step 4 is repeated until no more triangles are added.

Once enough nodes have been added so that internal nodes will no longer pass through the boundary nodes, the relaxation algorithm is run using all of the boundary nodes in both the original definition plus all those added in order to keep internal nodes from passing through the boundary nodes.

MATERIAL PROPERTIES

Material properties include the elastic coefficients of the material, the material density, and the breaking strength of the material. Material properties are defined for the global system, but may be modified for regions within the material. In the general force equilibrium equations, the values of the spring constant and the typical size of a bond (spring or beam) are immaterial for the equilibrium configuration, but are essential for the interpretation of the stresses and strains in terms of physical quantities. All forces calculated in the rescaled model must therefore be multiplied by Ewl in two dimensions and by El^2 in three

dimensions.

Local variations of the elastic coefficients are handled by changing the local values of k_i , the spring constant for node i , as explained above. The values
5 $k_i = 1$ implies that the Young's modulus for node i is the same as the overall Young's modulus. The simulation model allows the overall spring constant k to be changed to a value other than unity but in the preferred embodiment, a value of one is used.

10 The distribution of breaking thresholds is used to tune the behavior of the material from a brittle material for a narrow distribution to a more ductile behavior for a wider distribution. The distribution incorporates the effects of different lithologies, the degree of consolidation, cohesion within the material, disorder, and the effect of varying strain-rates during deformation. The breaking
15 threshold distribution provides the force $f_{i,j}^c$ for which a given spring will break. The values are drawn randomly from the distribution initially and do not change during the simulation. In a preferred embodiment of the invention, the distribution of breaking thresholds is a Gaussian distribution. In an alternated embodiment of the invention, the distribution is a Weibull distribution. For the
20 aerial model, comparisons between simulation experiments and physical model studies suggest that the Gaussian distribution with $\mu = 0.15$ and $\sigma = 0.05$ provides a good match for several field cases.

For the beam model, an additional distribution of breaking thresholds is included in the present invention. For each beam, the threshold values $m_{i,j}^c$ are drawn from the moment threshold distribution. In a preferred embodiment of the invention, a single Gaussian distribution is used to describe the full range of lithologies, inhomogeneities, and rate dependent effects. In alternate embodiments of the invention, a plurality of distributions is used and distributions other than Gaussian may be used.

Those versed in the art would recognize that the condition for the breaking of a beam depends upon both the normal force and the moment in the beam. In a preferred embodiment of the invention, a *von Mises* type breaking criterion is used. This requires determination of

$$M = \max \left(\frac{f_{i,j}}{f_{i,j}^c}, \frac{m_{i,j}}{m_{i,j}^c}, \frac{m_{j,d}}{m_{j,d}^c} \right) \quad (11).$$

A beam breaks if $M > 1$, and the beam with the largest value of M is broken first.

The breaking thresholds may be changed for regions within the simulated material. For bonds extending beyond the boundaries of a region from particles within the region, the breaking thresholds are drawn from the distributions within the region. The definition of the regions depends on the dimensionality of the

system.

In two dimensions, a region is defined by a closed loop around its boundary. The loop is defined as a piecewise linear curve, specified by the coordinates x_n for $n = 1, 2, 3, \dots M$, with the next point in the sequence after M being 1. A node at a position x_i is established to be either within or outside a region by angular integration (summing) of $\phi = \sum \phi_n$ where ϕ_n is the angle between $\vec{x}_n - \vec{x}$ and $\vec{x}_{n+1} - \vec{x}_i$. If $\phi = k2\pi$, the point is inside the closed curve and if $\phi \neq 0$, the point is outside the closed curve. This procedure works independently of the orientation of the curve and how many loops it has. The procedure is repeated for all nodes in the material to check whether they belong to a particular region.

Establishing enclosure in 3-D is a more elaborate procedure. The most commonly used type of volumetric definition is based on triangulation of the enclosing surface. This would, however, require a significantly more elaborate user interface for the definition of bounded regions. The present invention includes a simpler approach to establishing closure in 3-D. The interface allows the user to define a material region. This is done by displaying a set of points in each of N horizontal planes in the interface (here N depends on the number of layers of nodes chosen in 3D). The set of points in each plane defines an area for that material region. The number of points in each plane is the same so that a volume can be defined by a linear interpolation between points in adjacent planes.

The user may add or subtract points from any plane by pointing and clicking on a point in the interface. But points are added or subtracted in all of the planes at once, so that the number of nodes in each plane is always the same. So, for example, if a point is added in plane #2, a node is also added in planes 1, 3, 4, ..., N.

- 5 When complete, the input has defined a set of N planes, each containing M points. The enclosing surface for each plane, k, is defined by a set of closed loops $\{\mathbf{x}_{n,k}, n = 1, 2, \dots, M\}$. The set of loops traces out a surface for each $k = 1, 2, \dots, N$. The number of points, M, must be the same along each curve and corresponding points in consecutive surfaces are linked together to form the
- 10 surrounding surface.

During the material definition procedure, each particle is determined to be inside or outside the region based on a method similar to that used in two dimensions. Based on the z- position, z_i , of particle i , the enclosing curves above and below the particle i are found. A linear interpolation between the points along

15 the two curves is used to determine the shape of the curve at the height z_i of particle i . For two curves $\{\mathbf{x}_{n,k}\}$ with $k = K$ and $k = K+1$, the linear interpolation is found from

$$\mathbf{x}_{n,i} = \mathbf{x}_{n,K} c_n + \mathbf{x}_{n,K+1} (1 - c_n) \quad (12)$$

- 20 where c_n depends upon the vertical distance between the node i and the points

$$\mathbf{x}_{n,K} \text{ and } \mathbf{x}_{n,K+1};$$

$$c_n = \frac{z_i - z_{K,n}}{z_{K+1,n} - z_{K,n}} \quad (13)$$

Those versed in the art would recognize that among the commonly occurring subsurface material... involved in deformation, salt is unique in that over geologic time, it acts like a fluid and is capable of flowing. In a preferred embodiment of the invention, salt is defined only in a 2-D model. It is defined as a material region and all the nodes in the salt region are removed. The outer boundary of the salt region is set to be the initial border of the fluid used to represent the salt. The initial salt volume is set to correspond to the initial area of the salt material region. The salt material interacts only with the particles along the surface of the salt region. A force f_p acts on each node i along the fluid interface. The fluid pressure depends on the fluid volume through a linear compressibility relation:

$$P = P_0 + \kappa_p (V_0 - V) \quad (14)$$

where P_0 is the initial salt pressure, V_0 is the initial salt volume and κ_p is the salt compressibility.

Special care is taken at the outer boundaries of the simulated material. If the salt region extends beyond the simulated material, it is connected to the wall particles in order to form a closed outer surface around the salt fluid. This is depicted schematically in Fig. 4c. The boundary particles are indicated by the dashed circles 373 while the material particles outside the salt region 375 are

denoted by the solid circles 371.

In an alternate embodiment of the invention, the flow of the salt without fracturing is handled by a finite element code. While this results in more accurate simulations, it comes at the cost of greater computation time.

CONDITIONING OF THE MODEL

Returning now to Fig. 1, the process of conditioning the model is now discussed. In any model in which the modified Dynamic Range Relaxation method is applied, the final fracture (or fault) pattern depends on the order and the positions at which fractures (or faults) appear, because the formation of faults and fractures depends on the local stress field in the rock. For convenience, when the term fracture is used in this application, it is to be understood that faults are included, and vice-versa. This stress field, in turn, depends on the position and size of all faults and fractures. In order to produce a prediction of faulting on a finer scale than that known from field observations, 105 in Fig. 1 (e.g., from seismic data, geologic observations or from well information), the physical model must reproduce the main faults during the simulation in such a way that they are grown "naturally" during the deformation. The basic problem then is to find a method for determining the initial conditions of the rock material that produces the large-scale features known to be present, and, in addition, produce finer scale deformation that is not readily observable in the field.

As noted above, in the present model, the subsurface is represented by a set of nodes having elastic interconnection with adjoining nodes. The material properties of the material are described by the material properties of each node and each bond connecting the nodes. Each node is described by its geometrical size and the elastic constants of its interactions with other nodes. Each bond is described by its length, its elastic properties and by a breaking threshold that specify the maximum stresses (stretching, bending, torque, etc.) for the bond to break. If a bond breaks, it is removed from the model and the position of the broken bond is interpreted as fracture.

In order to force the model to produce particular faults in the final configuration, the initial configuration is modified. As noted above, field observations provide positions of the large-scale final deformation that the model must produce. The initial position of the faults is found by mapping the final position backwards in time. This is sometimes called palinspastic reconstruction. A trained geological interpreter is able to do this using certain well-known physical principles. For example, most geologically occurring formations have a relatively low strain value at fracturing, so that the total volume of rock must remain substantially constant during the reconstruction. In addition, once a rock is fractured, it must remain fractured in a forward simulation, so that in a palinspastic reconstruction running backwards in time, new faults cannot appear. In addition, the Anticipate process 111 in Fig. 1 discussed below makes it possible to get a fast approximate solution of the final deformation. This greatly reduces

the experimentation required for an initial model. In any case, even the little experimentation that may be necessary is useful because each initial model may provide a somewhat different output for the minor faulting and fracturing that result. The resulting ensemble of outputs provides a range of possible scenarios for development of the hydrocarbon reservoir.

In addition to having an initial model that approximates the major faults, the general variation of the material properties must also be known. This can also be found by reverse modeling from the final deformation, and input into the model, as elastic properties and distributions of breaking thresholds.

The next step is to condition the fractures in this initial model. This is done by making it more probable that during the forward modeling, the fractures will appear in the vicinity of the positions defined initially. However, if the actual fracture positions are input into the initial model, the effect of interaction between the fractures would in the forward modeling would be relatively minor and the simulation would not produce the correct final fault pattern. Accordingly, in the present invention, the material properties in the vicinity of the initial fault positions are modified.

Conditioning occurs along piecewise linear curves in two dimensions, and piecewise linear surfaces in 3-D. Conditioning is implemented as a weakening of all bonds that intersect this weakening curve or surface. The weakening depends on the distance from the center of the curve/surface, in order to ensure that the

conditioned fracture grows from a center seed during the simulation.

Initially, the center of mass of the conditioning line or surface x_i is found.

The breaking threshold $f_{i,j}$ of the bond from node i to node j is then weakened by

5 a factor $f(r)$

$$f_{i,j} \rightarrow f_{i,j} f(r) \quad (15)$$

The weakening function increases from a value of 0 at the center, i.e., the bond will definitely break, to a value of 1 (no weakening) at a surface, called the rim of the conditioning surface. In the preferred embodiment of the invention, the

10 weakening function is linear, although other forms may be used in alternate embodiments.

Intersections between the piecewise linear curve and a linear bond are readily resolved in 2-D models. In 3-D, the conditioning surface is specified by a

15 series of lines $\{x_{i,k}\}$. Each line has a constant number of points: $i=1, 2, \dots, I$.

Each point $\{x_{i,k}\}$ in the line k is connected to the points $x_{i,k-1}$ and $x_{i,k+1}$. This

produces a series of surface elements defined by four corner points. Each rectangular surface element is divided into two triangles in order to determine possible intersections with bonds in the lattice. Possible intersections are found

20 using standard methods of linear algebra.

THE ANTICIPATE PROCESS

Another novel feature of the present invention is the ability to get a quick

and dirty look (anticipate) at the result of an applied deformation. This step is denoted at 111 in Fig. 1 and is best understood by reference to Fig. 5.

Denoted is a portion of the grid, represented by points 401, 402, 403 . . .

- 5 407. An initial deformation is applied to points 402 and 403 so that they end up at the locations specified by 402' and 403'. The anticipate function gives an approximate solution to the post-deformation position of the remaining points in the lattice as a result of this applied deformation, assuming that they are points on an infinitely elastic substrate (or space).

10

Denoting by $r_{\{0,i\}}^{\mathbf{x}}$ the initial positions of the n points where the deformation is applied and by r_i the ending position of the points where deformation is applied, a displacement of these points is defined by $d_i = r_i - r_{\{0,i\}}^{\mathbf{x}}$. In the example of Fig. 5, the initial points are 402, 403 and the final positions are 402', 403' and the
15 displacements are the vectors joining 402 to 402' and 403 to 403'.

For an arbitrary point initially at r_0 , the end position is given by

$$r_i^{\mathbf{x}} = r_0^{\mathbf{x}} + \sum_{i=1}^n L_i e^{-x_i} d_i \quad (16)$$

- In eq. (16), x_i is the distance between the position of the point r_0 in the
20 undeformed lattice and the end position $r_{\{0,i\}}^{\mathbf{x}}$ of the i -th arrow, i.e.,

$$x = \left| r_0^{\mathbf{x}} - r_{\{0,i\}}^{\mathbf{x}} \right|$$

In eq. 16, the matrix L_i is given by

$$L_i = \begin{bmatrix} Lx_i & 0 & 0 \\ 0 & ly_i & 0 \\ 0 & 0 & lz_i \end{bmatrix}, i = 1, 2, 3, \dots, n$$

Lx_i , ly_i , and lz_i are given by the solution of three sets of n equations with $3n$

5 unknowns:

$$r_j^x = r_{\{0,j\}}^x + \sum_{i=1}^n L_i e^{|\{0,j\} - \{i,j\}|} d_i^x, \quad j = 1, 2, 3, \dots, n$$

(18)

In addition to local deformations, a number of uniform/global movements
 10 may be specified (extension, shear or rotations). For extension and shear, a line of
 no deformation is specified together with angles and total percentage deformation.
 For rotation (only 2-D models) a center of rotation, an angle and a radius of the
 area to be rotated is specified. This is sometimes referred to as a vortex. The
 amount of rotation decreases exponentially with the ratio of the distance from the
 15 specified center of rotation to the specified radius.

In addition to the use described above, in a preferred embodiment of the
 invention, the anticipate step is also applied automatically in the background when
 the Dynamic Range Relaxation Algorithm is run. As noted above, deformations
 20 are specified by the user at selected points in the model. The "background"
 running of the anticipate step interpolates the user defined deformation to every
 point on the boundary and/or substrate as boundary condition for the relaxation

algorithm.

THE GRAPHICAL USER INTERFACE

The Graphical User Interface (GUI) of the present invention is, as the
5 name implies, a computer program that enables the user to define the model,
manipulate the deformation process and view the results. The main panel for the
GUI is illustrated in **Fig. 6**. It has a number of pull-down menus. Note that the
labels assigned to the various buttons in the entire application and discussed
herein are for convenience only and are not intended to be a limitation. The
10 various options of pull-down menus are described here without actual illustrations
of the pull-down options.

The file menu **501** includes the following options that are typical of many
computer programs:

- 15 1. **New** erases all deformation history information.
2. **Open** produces a standard file selector that lets the user read in
existing files.
3. **Delete** allows the user to delete existing files.
4. **Save** allows the user to save the existing file.
- 20 5. **Save as** allows the user to save the existing file and specify the
name under which it is to be saved.
6. **Print** allows the creation of an image file in a specified format. In
a preferred embodiment of the invention, the format is a .gif file.

Still referring to **Fig. 6**, the **Edit** menu **503** has the following options:

1. **Clear item** removes one element of the deformation history, such as an extension or a region, based on the currently selected item.
2. **Clear all** removes all elements within a method, such as all material regions, based on the currently selected method.
3. **Remove era** removes an entire era based on the currently selected method. Eras are discussed below with reference to the **timeline 521**.
4. **Preferences** produces a separate panel used to set memory parameters and other preferences.

The **View** menu **505** provides the following options:

1. **Set XY/XZ ratio** lets the user stretch or shrink the section that is displayed in the graphics display.
2. **Plane view** switches to a display mode in which the displayed section is viewed at an angle of 90^0 .
3. **3D view** switches to a display mode in which the viewpoint can be chosen freely by the user.

The **Parameter** menu **507** allows the user to select from a list including:

1. **View parameters** produces a panel displaying information about a setup.
2. **Edit parameters** allows the user to edit the run parameters. This is discussed below with reference to **Fig. 8**.
3. **Set defaults** sets default parameters and switches to an areal

simulation mode.

The **Project** menu 509 includes the following options:

1. **Anticipate** lets the user anticipate the outcome of the simulation
5 assuming that the deformed section is made of rubber that never breaks. This has
been discussed above with reference to 111 in Fig. 1.
2. **Make method** allows the user to define a method of simulation
and assigns a button to the selected method.
3. **Remove method** deletes the assignment made in (2) immediately
10 above.

The **Run** menu 511 includes:

1. **Start Run** starts a simulation
2. **Job Control** produces a panel with a list of currently running
15 simulations.

The **Animate** menu includes:

1. **Make movie** allows the user to select pattern files to be included in
an animation.
- 20 2. **Open Movie** lets the user watch an animation of the simulation
results.

The **Run** indicator 515 shows either 'FRAM' when no simulation is
running or shows a fracture pattern that changes with time if a simulation is

running.

The **mode selector 517**(not do be confused with the mode of definition of a model discussed above) allows operation in either the **Setup Run** or the

- 5 **Analyze Run**. Depending upon the selection, some menu entries will be disengaged (grayed out) and other are engaged.

The **Method Button Array 519**. A method is a set of data that specifies a part of a deformation history—either a deformation method, a conditioning

- 10 method of a material method. If the user clicks on one of the active method buttons, the cursor changes shape and the user may specify a **timeline** discussed below. The method button array shows **deformation method buttons**, **conditioning method buttons** or **material method buttons**. The method mode is changed by clicking on the appropriate **timeline**. Initially, the method button
- 15 array contains only very few buttons, representing standard methods such as the “Empty deformation,” a formation without any extensions or regions. Another standard method is the “Empty condition,” a conditioning method without any fractures. Four other standard methods are the “Brittle material, the “Soft material”, the “Very soft material”, and “Sand.”

- 20 The user may build a library of methods and save them.

The **Timeline 521** is used only in the setup mode. It comprises horizontal fields labeled “Deformation,” “Condition,” and “Material”. If the user clicks on any of the timeline fields, the **method button array 519** shows the method

buttons that correspond to the selected mode and a corresponding method editor or
"toolbox" appears on the bottom left of the screen (not shown). The horizontal
fields may be further subdivided into slots. Each slot represents one method and a
default value of one slot per field is set. A column of slots together defines one
5 deformation era. In a preferred embodiment of the invention, up to three
deformation eras may be specified. If multiple eras are specified, the simulator
processes the first of them. The eras represent deformation events that occur
sequentially. An alternate embodiment of the invention includes a restart feature
so that processing may continue from one run to another without losing the benefit
10 of earlier computer runs.

Turning now to Fig. 7, the graphics display window in the center part of
the screen is illustrated. This is used to set up a deformation history and to view
the resulting fault patterns. Two view modes may be used, "Plane" and "3-D".
15 The latter mode enables a free choice of the viewpoint in 3-D space. The former
limits the viewpoint to the xy , yz , or zx planes. The user may switch from one
view mode to the other by using either the menu entries in **View menu 505** in Fig.
6 or by using the **Screen button 601** in the graphics display window. In the cross-
sectional and areal simulation mode, this **screen button 601** is the only one in the
20 left hand of the graphics display. In 3-D simulation mode additional buttons and a
text window are visible. In 3-D simulation, the simulated section is conceptually
divided into horizontal "planes"; the text window **603** indicates which plane is
under consideration. Two arrow buttons **605** can be used to leaf through the
planes. An additional button **607** enables the user to switch between "one-plane"

and "all-planes" display.

Button 609 in the graphics display is used to switch to "pointer" cursor mode. In this cursor mode, the cursor takes the shape of an arrow, and items such as deformation arrows can be selected by clicking (Geri says "I would remove that sentence [the previous sentence that I marked out] because although it is true for the implementation FramView_F that is under consideration, it will not be true in future implementations.") The adjacent button 611 switches the cursor to the "hand" mode. In the hand cursor mode, the viewpoint may be changed in three dimensions by moving the mouse while holding the left button or the center button pressed. Additional buttons are provided for help (613), set home viewpoint (617), go to home viewpoint (615), show everything (619), and toggle perspective. 617 sets the current view as the "home view" so that when 615 is pushed, the display automatically returns to the "home view" without the user having to rotate or move the object back manually to it's "home view" location. 618, (the button not labeled below the 617 button) changes the view point so that all of the current figure fits within the display. This button is used if one has zoomed in so far that all of the object is no longer visible on the screen. 618 automatically zooms out so that all of the object fits in the window. 627 toggles between a perspective view and non-perspective view. A perspective view has a focal point; a non-perspective view does not. X (621), Y(623), and Z (625) set the views to be on the X, Y, and Z axes respectively. 619 defines a pointed that can be positioned on the screen to define the center of the view. That is, a cross symbol appears when this button is pushed. It can be moved in the viewing

window to a desired point. When the left mouse button is pushed again, the center of the cross symbol becomes the center of the viewing window.

On the lower frame of the graphics display window, wheels are shown for
5 changing the point of view in an alternative manner. Alternatively, when button
611 is pushed, a "hand" appears in the window display. If the left or center mouse
button is held down while moving the mouse, the "hand" drags the object in the
display window, either rotating it (if the left mouse button is pushed) or moving it
(without rotation - if the center mouse button is pushed).

10

Within the graphics display, a number of editing steps may be carried out.
For example, the position of a deformation arrow of a deformation region, a
conditioning fracture, or a material region may be moved. This is accomplished
by switching to the **pointer** cursor mode 609, and clicking on the object to be
15 moved. Holding the mouse button depressed, the object may be moved to its final
destination. In a deformation method, **localized extensions** are represented by
single arrows with a footprint and a tip. By clicking on either the tip or the foot
and holding the left mouse button, the position can be moved. By clicking on the
body of the arrow, the entire arrow may be moved.

20

Uniform extensions and **shears** are represented by double arrows. By
clicking on one of the tips and holding down the left mouse button, the percentage
of extension may be adjusted. By clicking on the center point and holding down
the left mouse button, the entire double arrow may be moved. The angle of the

double arrow with respect to vertical is set by clicking on one of the arrow bodies and holding the mouse depressed. Among other items that may be edit graphically are the center of rotation, the vertices of deformation regions, material regions and conditioning fractures. A vortex may be added or removed to a selected region or fracture.

The parameter panel

The parameter panel pops up if the **Edit parameter** button is selected at 507 in Fig. 6. Turning now to Fig. 8, there are four control buttons at the bottom of the parameter panel. The **factory settings 651** sets the parameters to their default values and switches to areal simulation mode. **Done 653** accepts the settings and closes the parameter panel. **Apply 655** accepts the settings without closing, and **Cancel 657** ignores the settings and closes the window.

The top section of the panel 659 includes a button 661 for setting the random number generator used to set up the network of nodes. Alternatively, the **set new seed** button 663 sets up a random number based upon the machine clock. The mode button 665 sets the model to areal, cross-sectional or 3-D model. Button 667 selects the type of connection between the nodes, i.e., to either **spring** or **beam**.

In the second section of the panel 671, button 673 enables the user to switch between a newly generated lattice and an "old" lattice from an earlier simulation. The type of lattice is set using button 675 to be either triangular or

disordered. If a disordered lattice is selected, the disorder parameter button 677 is engaged. The lattice size in the x direction is set using button 679 and the sizes in the y and z directions are set using the aspect ratio sliders 681 and 683.

Optionally, the number of planes in the vertical direction may be set using the

5 button 685.

As noted above, in the cross-sectional and 3-D simulations, gravity is taken into account. The gravity constant is set in window 691.

10 During the simulation, nodes may come close to each other. To avoid this unphysical "compression", the preferred embodiment of the invention includes the repulsion toggle switch 693. This may be turned off by the user.

As discussed above, the simulation in the present invention is based upon a
15 relaxation scheme. Convergence of the relaxation scheme is controlled by parameters set in the **relaxation threshold 695**, **over-relaxation factor 697**, **maximum movement during relaxation 699** and **time step 701** buttons. These parameters have been discussed above with reference to 115 in Fig. 1. If a beam simulation is used 667, additional parameters are set in **angular relaxation 703**,
20 **and angular over-relaxation factors 705**. These have also been discussed above with reference to 115 in Fig. 1. The thresholds greatly influence the speed of the simulation and for initial simulation work with a model, a high threshold of 0.0001 is recommended. For subsequent detailed simulation, the threshold may be lowered.

5
10
The **deformation editor** is invoked at 521 in Fig. 6. The deformation editor is used to specify the deformation to be applied in the simulation. The screen display 751 is shown in Fig. 9a. The top row of buttons is used to introduce extensions and rotations into the model. The **localized extension** button 753 is labeled with a single arrow. The two adjacent buttons 755, 757 represent **uniform extension** and **uniform compression**. The buttons labeled with opposing arrows 759, 761 represent uniform right and left lateral shear respectively. The button 763 is used to introduce rotation. The button 765 is used to introduce a **deformation region** in the areal simulation mode or on the lowest plane in 3-D simulation. The adjacent buttons 767, 769 are used to define a translation and rotation to the region defined by 765. In the simulation, the region defined by 765 will move stiffly according to the specified translation and rotation.

15
The button 771 is used to introduce a **deformation region** in the cross-sectional mode or on the higher planes in 3-D simulation mode. These regions can include only boundary nodes. The other three buttons 773, 775, 777 are used to assign a translation, rotation and tilt to the region.

20
The present invention includes the ability to use a previously defined image in the deformation editor. When the **import GIF** button 771 is pressed, a .gif file may be read in and superimposed on the model grid. The image may be obtained from geologic or seismic maps of a subsurface region. The image may be toggled on and off and its brightness may be adjusted using buttons 773, 775.

The button **GIF geometry** produces a window that can be used to adjust the position of the background image. Included are horizontal and vertical translation and rotation. The **motion constraint** button 779 is used to constrain the movement of the cursor. The **deformation details** button 779 leads to another pop-up menu that gives further information about the exact position and settings of a selected image.

Fig. 9b shows an example a setup for a 3-D simulation with two deformation regions 781, 783 in the lowest plane, each associated with a stiff translation.

The **Conditioning Editor** is invoked at 521 in **Fig. 6**.

The conditioning editor is used to condition the model as discussed above in reference to 107 in **Fig. 1**. The display menu 801 for the conditioning editor includes a **fault** button 803 to introduce a new pre-existing fault into the lattice. By default, the new fault is placed in the center of the lattice and has two vertices. The user may add more vertices by selecting the fracture and clicking on the right mouse button. The position of the currently selected vortex is indicated in the **Vertex X** and text windows 803, 805. By default, the new fault weakens the lattice by 100%. The user may adjust the weakening using the **bond weakening slider** 807. A weakening of 0% has no effect. The linear and exponential transition buttons are used to define the decay of the weakening of the bonds away from the fault. This was discussed above with reference to 107 in **Fig. 1**. The **import GIF** button 811 selects an image file. The toggle **show** 813, **brightness**

815 and **GIF geometry 817** are similar to those described above in the **Deformation Editor** in reference to **Fig. 9a**.

An alternative embodiment of the invention reads in preexisting fault
5 patterns (importing) as a data file, such as an ASCII-file, in which sets of vertices
are specified. This is done using the **Import fault map button 819**. Both
specified faults and imported faults can be translated, stretched or shrunk using
the **Global Fault geometry button 821**. An example of an imported fault is
shown in **Fig. 11** wherein there are two faults **827** and **829** indicated, with the
10 fault **829** characterized by vertices **831**.

The material editor is invoked at **521** in **Fig. 6**.

The material editor is used to specify material methods. A material
method always contains a base material that covers the entire lattice. The material
15 editor is used to set the properties of the base region. These properties translate
directly into the statistical distributions that are used to set up the network of
springs and nodes that underlies the simulation. In addition, material regions can
be defined that cover only part of the lattice. The properties of these regions
supersede the properties of the base region. Note that if these "higher order"
20 regions overlap, the material properties depend upon the order of their
specification, with the last defined material properties prevailing.

The two buttons **851**, **853**, labeled as "R" and "S", are used to introduce
the higher order regions. "R" stands for a rock region and "S" stands for a salt

region. In a preferred embodiment of the invention, there is only one salt region, though in alternate embodiments of the invention, more than one salt region may be defined. From the standpoint of simulation, rock and salt differ fundamentally in that the rock can be modeled as a network of springs and nodes (or beams and nodes) whereas salt cannot. In the setup, this is reflected by the fact that the salt properties take on “unphysical” values by default and cannot be changed to “reasonable” ones.

By default, each new “higher order” region has the shape of a square and is located in the center of the lattice. The shape and position may be manipulated as discussed above. The **LinBondThrs’Mean** button **855** is used to set the mean linear extension breaking threshold of bonds. The **LinBondThrs’Sdev** **857** is used to set the standard deviation of the breaking threshold of springs. If this number is large relative to the mean (0.05), the region may be considered a soft material; if it is small (0.01), the region may be considered brittle. The **Density** button **859** is used only if gravity is relevant and sets the density of the nodes. The **ShearStressThrs’Mean** and **ShearStressThrs’Sdev** buttons **861**, **863** are used to set the mean shear stress breaking threshold and the standard deviation thereof for a beam model. The **ExcessHght** button **865** sets the excess height, a quality used in cross-sectional simulation mode in order to restrain the motion of boundary nodes, and specifies the height of the side walls in units of the material thickness. The **force constants** button **867** produces a separate window wherein additional material properties are specified.

The material force constant panel

This panel, shown in Fig. 13, appears when the **Force constants** button 867 in Fig. 12 is pressed. It contains a number of text windows used to specify the constants that control the faulting properties of the material. The **Rel. Linear** 5 **force constant k** is the local force relative to the overall force constant k_0 . For the base material, the value of Young's modulus E_0 is given. For other regions consisting of different materials with different elastic properties, the relative changes are given by k . Thus, for a region with an elastic constant E , the relative linear force constant is $k = E/E_0$. It is recommended that in the base region, the 10 value should always be set equal to 1.0 to ensure stability of the simulation code. In "higher order" material regions, this can take a value different from 1.0 for stronger or weaker materials than the base material. If $k=0$, then that region will have no elastic interactions and the simulation will produce unphysical results.

15 **Rel. Shear force Constant k_s 905** is a scale factor for all shear force constants, i.e., those that are relevant only to a beam simulation model. Generally, k_s is a function of Poisson's ratio ν and the beam thickness a , which is an additional free parameter. As would be known to those versed in the art, the value of k_s must not be set to arbitrary values as this may correspond to unphysical 20 values of Poisson's ratio. k_s is given by

$$k_s = \frac{1}{2} \frac{1}{2(1+\nu) + \left(\frac{1}{a^2}\right)} \quad (17)$$

Theoretically, $-1 < \nu < 1/2$ and $0 < a < 1$. However, for most materials of geologic interest, $\nu > 0$. It is recommended that the user of the invention set values such

that $0.1 < \nu < 0.3$ and $0.5 < a < 1.0$

Gamma 905 is also a parameter related to beam bending. It too is related to Poisson's ratio and the beam thickness. It is given by

$$\Gamma = 2(1 + \nu) \frac{1}{12} \left(\frac{a}{l} \right)^2 \quad (18)$$

Substrate attachment force k_0 907 gives the strength of the substrate attachment springs relative to the internode springs. For areal simulations, a value larger than 0 must be chosen in order to provide an imposed stress. However, for cross-sectional and 3-D simulations, the value is fixed to 0 because for these systems an attachment to an underlying substrate would impose an unphysical boundary condition. In the beam model, the substrate attachment can also carry torques, and each node is attached to the substrate by a torsional spring, with torque spring constant **k_{s0} 909** relative to the internode spring constant.

Wall attachment force constants 909 define the attachment of the walls to the boundary nodes. The force constants are measured in units of the background force constant **k_0** . A positive value indicates an attractive force while a negative value indicates a repulsive force.

Salt compressibility 909 is the linear compressibility of the salt relative to the Young's modulus elasticity of the simulated material. Values between 0.5 and 0.9 are recommended.

Analysis Editor

The analysis editor is the main tool to control the display of fault patterns resulting from simulations. The main features are:

1. **Redraw pattern** causes the graphic display to be cleared and a
5 fault pattern is displayed again.
2. **Show bonds** determines whether bonds connecting the nodes are displayed.
3. **Render quality** controls the quality (detail) of display of the fault patterns.
- 10 4. **Show faults** controls the display of faults.
5. **Show stress map** engages the computation of stresses in the model. Stresses may be displayed in color displays of a selected component of stress or by vector displays. The user has control over the scale of the displays.

- 15 While the foregoing disclosure is directed to the preferred embodiments of the invention, various modifications will be apparent to those skilled in the art. It is intended that all variations within the scope and spirit of the appended claims be embraced by the foregoing disclosure.
